Abstract

In this study, we report the three-point flexural strength and fracture toughness of monolithic hafnium carbide up to 2000 °C. HfC with different grain sizes was consolidated using the spark plasma sintering method. Coarse-grained monoliths showed a weak dependence on the strain rate during high-temperature tests at 1600 °C–2000 °C. In contrast, results for the ceramics with a grain size below 20 μm indicated a positive dependence of the yield strength vs strain rate. This allowed us to identify the activation energy for high-temperature deformation in flexure as 370 kJ/mol. This level of activation energy is in satisfactory agreement with reports about the diffusion of C in hafnium carbide.

Keywords: hafnium carbide; grain size; flexural strength; high-temperature materials.

1 Introduction

The design of next-generation hypersonic flight vehicles has raised interest in the development of materials that can operate in extreme environments. Under such conditions, thermal protection structures are required to operate in air/vacuum at temperatures that can exceed 2000 °C, thus components are not only required to have very high melting points, but also oxidation and ablation resistance. From the vast array of structural materials, there is a limited number of materials (compounds and elements) that meet requirements for the described working conditions in which the so-called ultra-high temperature ceramics (UHTCs) are included [1]. Typically, the group IVB and VB bulk carbides, nitrides, and borides belong to the UHTCs family. Monolithic transition metal carbides act as a backbone for the UHTC family [2–4], as HfC–TaC [5,6], for instance, have the highest reported melting point for any compound. Recently, there has been much particular attention paid to the high-entropy ceramics or high-entropy carbides [7–9]. As mentioned for the HfC–TaC system, some extreme properties can be explored and potentially utilized for other members of the UHTC family. Having said that, in [7], it has been noted that only selected studies have reported the strength properties of HfC [10–13]. This is thought to be due to its high-melting point (3900 °C), and thus the unavoidable presence of HfO₂ during consolidation at extremely high temperatures [13,14]. Nevertheless, it

1
2
3
4 was analyzed that in some instances HfC bulks showed an increase in strength with
5
6
7 an increase in temperature, suggesting that microplastic deformation is being
8
9
10 activated in this relatively brittle metal carbide [13].
11

12
13 This provides the potential of being used at temperatures approaching 2000 °C,
14
15 however, essentially the low diffusivity in the monolithic UHTCs in general [15],
16
17 and for HfC in particular, indicates that processing of the bulk additive free HfC
18
19 [13,14] remains a challenge. In order to produce highly dense monolithic hafnium
20
21 carbide in this study, we used a commercial Zr-free HfC and employed spark-plasma
22
23 sintering to promote densification [7–9, 16].
24
25
26
27
28
29

30 This study, for the first time, explores the microstructure evaluation during multiple
31
32 sintering runs of HfC, which have been made in order to determine the flexural
33
34 strength, hardness, toughness and Young's modulus. Flexural strength at elevated
35
36 temperatures was evaluated for HfC bulks with different grain sizes. High-
37
38 temperature deformation in flexure was evaluated for specimens which have a strong
39
40 correlation between the strain rate and yield strength at 1800 °C–2000 °C.

50 **2 Materials and Methods**

51
52 Commercially-available HfC powder (Alfa Aesar, Lot #W19E52), which consists of
53
54 micrometer aggregates of sub-micrometer ~300 nm crystallites was used as the
55
56 starting material. The received untreated powder was used for consolidation using
57
58
59
60
61
62
63
64
65

1
2
3
4 the spark plasma sintering (SPS) method. The SPS experiments were conducted
5
6
7 using the 'Dr. Sinter' 1050 (Sumitomo, Japan) unit with a 30-mm die, as a rule, 20
8
9
10 to 25 g batches were used.

11
12
13 The schedule for the hafnium carbide specimens prepared in this study had four
14
15 major steps: (1) heating to 900 °C in four minutes following (2) a 50 °C/min heating
16
17
18 to densification temperature within the 1600 °C to 2100 °C range. The dwell
19
20
21 between 1 and 20 minutes at the densification temperature was used. The third step
22
23
24 included cooling to 600 °C in 20 minutes. The pressure of 32 kN was maintained
25
26
27 during the consolidation and cooling stages. Argon gas at the flow rate of 2 L/min
28
29
30 was used.

31
32
33 An X-ray diffraction (XRD) analysis (D8 Advance, Bruker, Karlsruhe, Germany)
34
35 was performed on the polished surfaces of the bars after the flexural tests using Cu-
36
37
38 $K\alpha$ radiation. The intensity data were collected over the 2θ range of 20°–145°, in
39
40
41 steps of 0.02–0.05° using a sampling time of 10 s for each step. The software used
42
43
44 for refinement was TOPAS (TOPAS Ver. 4.2, Bruker AXS, Germany). Instrumental
45
46
47 broadening was determined using a NIST 660b LaB₆ standard run under the same
48
49
50 conditions for each carbide sample.

51
52
53 The structural characteristics of the hafnium carbide ceramics were studied using
54
55
56 scanning electron microscopy (SEM, JCM-6000, JEOL) with secondary (SE) or
57
58
59 backscattered electrons (BSE mode).
60
61
62
63
64
65

1
2
3
4 The three-point flexural strength was determined using rectangular blocks (2×2×25,
5 2×2.5×25 mm) and the strength testing equipment were previously described in
6
7 detail [17]. A span of 16 mm was used. The fracture toughness of the ceramics was
8
9 evaluated by the specimen bending testing which contained a single edge through-
10
11 thickness notch following ASTM C1421–10. Details of the testing configuration and
12
13 the notch profile are presented in ref. [18]. We evaluated the elastic modulus (E_f)
14
15 for the tests from the linear portion of the load-displacement curve using the
16
17 procedure described in ASTM E111–04 [19].
18
19
20
21
22
23
24
25
26

27 To evaluate the strain dependence of the yield stress [20] for the hafnium carbide,
28
29 tests were performed using loading rates of 0.1 to 25 mm/min (1600 °C–2000 °C)
30
31 and low temperature tests were performed at the loading rate of 0.5 mm/min. Tests
32
33 at elevated temperatures were performed in argon.
34
35
36
37

38 The hardness was determined by an MMT-7 Vickers hardness tester (Matsuzawa
39
40 MMT-7; Matsuzawa SEIKI Co., Ltd., Tokyo, Japan) using a load of 9.8 N and 98 N
41
42 with a dwell time of 15 s following the standard procedure (ASTM C 1327–15).

50 **3 Results and Discussion**

51 *3.1 Phase analysis of hafnium carbide bulks*

52
53 X-ray studies revealed that the lattice parameters of hafnium carbide varied between
54
55 4.6399 Å and 4.6414 Å for the powder and bulk, respectively. The initial powder
56
57
58
59
60
61
62
63
64
65

1
2
3
4 showed only peaks of Hf and C during EDX, while faint peaks of O and Nb (~0.2
5
6 mol.%) were noted. Traces of other metals in the powder or consolidated HfC bulks
7
8 have not been identified. The XRD results revealed that the majority of the bulk
9
10 specimens (within >80 measurements) can be refined using the lattice parameter of
11
12 $a = 4.640 \pm 0.002 \text{ \AA}$ (**Figures 1,2**). Traces of free carbon ((002) peak at 26.5°) were
13
14 seldomly observed even for the mirror-polished specimens. The minor presence of
15
16 cubic oxide was rarely identified using the (200) peak and lattice parameter of
17
18 $5.14 \pm 0.01 \text{ \AA}$. Based on the lattice parameter, the X-ray density was evaluated as
19
20 12.66 g/cm^3 . The porosity was identified by SEM using a polished specimens and
21
22 FIJI software [21]. The bulk density was measured using Archimedes method, and
23
24 neither of the specimens, including those with a porosity below 0.02% by an SEM
25
26 analysis approached the number. According to the reference literature, the
27
28 theoretical density of HfC is 12.20 g/cm^3 [2,4,15]. However, this value appears to be
29
30 an underestimation, as one can see from **Figure 3** that the bulk density of the fully
31
32 dense material was 12.40 g/cm^3 (97.9% of X-ray density). For this study, the value
33
34 of 12.40 g/cm^3 was accepted as the theoretical density (TD) for evaluation of the
35
36 relative density. Similar value has been used in [22].

3.2 *Densification and grain growth of hafnium carbide*

1
2
3
4 **Figure 4** illustrates data of the mean grain size as a function of the relative density.

5
6
7 One can see that only a slight coarsening was observed below 75 % TD (see **Figure**
8
9 **5**), while grain growth followed an exponential dependence after a threshold density
10
11 of 97% was achieved. Large grains, up to 100–200 μm , were frequently observed
12
13 for the specimens after SPS above 2000 $^{\circ}\text{C}$. One should bear in mind that the original
14
15 powder was prepared by a wet chemical method and was not milled. The powder
16
17 consisted of crystallites of ~ 300 nm assembled into 1 to 6 μm aggregates.
18
19
20
21
22

23
24 Hence, the raw hafnium carbide powder acted as the initial source of porosity due to
25
26 the porosity that originated from the original aggregates [23]. As a rule, this porosity
27
28 is difficult to remove during processing (**Figure 6**), as such pores are entrapped in
29
30 the original large aggregates (up to 6 μm).
31
32

33
34 For most hafnium carbide specimens before reaching an ~ 15 μm grain size, pores
35
36 were located on the grain boundaries, while for the coarser grains pores were located
37
38 mostly inside the grains. These pores had a size between 1 and 2 μm and a spherical
39
40 shape, which are indications of the closing of the pore channels during the
41
42 intermediate stage of sintering [24]. Despite lengthy dwells up to 20 min at 2100 $^{\circ}\text{C}$,
43
44 these pores cannot be eliminated during solid-state sintering [25], as at temperatures
45
46 exceeding 2000 $^{\circ}\text{C}$, the grain growth would dominate over densification. An
47
48 exception would be promotion of the recrystallization during high-temperature
49
50 annealing, however such, reports are rather scarce for carbides [26]. In addition to
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 grain growth SPS at temperatures exceeding 2000 °C, it would result in the minor
5
6
7 presence of an oxide phase (black in BSE mode) in quantities up to 0.3 vol.%. For
8
9
10 polished specimens, the oxide is often located mainly between two adjunct grains in
11
12
13 the form of a fiber. Such an example is highlighted by the arrows in **Figure 6 (g)**.
14
15
16 No oxide grains were observed for the fine-grained materials or bulks consolidated
17
18
19 below 2000 °C.

20
21 From a wide spectrum of possible specimen data we selected four ceramics with
22
23
24 different grain sizes that are labeled as grades A, B, C and D in **Figure 4**.
25
26
27 Representative microstructures for the polished specimens and following flexural
28
29
30 tests at 2000 °C are presented in **Figure 6**.

31 32 33 34 35 *3.3 Mechanical properties of HfC ceramics*

36
37
38 The macroscopic hardness for bulk polycrystalline ceramics were reported in several
39
40
41 studies [2,4,13,22,27–32]. However, the majority of the tests presented in the
42
43
44 reference books were obtained using micro-loads from 50 to 200 g-force (0.49 N to
45
46
47 1.96 N). **Figure 7** summarizes the hardness measurements collected within the
48
49
50 present study. In general, with a load exceeding a 9.8 N hardness, the hafnium
51
52
53 carbide has a slight scattering between the different grades tests. However, at 98 N,
54
55
56 the hardness can be averaged as 15.2 ± 1.6 GPa. This provisional value is in good
57
58
59 agreement with the data of Silvestroni et al. [13].
60
61
62
63
64
65

1
2
3
4 The fracture toughness determined using notched specimens in flexure varied within
5
6
7 2.2 ± 0.4 MPa m^{1/2} for all the tested specimens. The exception was grade D, with the
8
9
10 coarsest grain size, as these ceramics had a slightly lower measured fracture
11
12
13 toughness (1.6 ± 0.1 MPa m^{1/2}). Furthermore, attempts to check the variation in the
14
15
16 fracture toughness for grade D at elevated temperatures between 1600 °C and
17
18
19 2000 °C indicated that the toughness remains constant up to 2000 °C at which a
20
21
22 value of 1.9 MPa m^{1/2} was measured.

23
24 The flexural strength showed a noticeable resemblance to the Hall-Petch relation and
25
26
27 varied between 300 and 600 MPa (**Figure 8**). The data of ref. [13] are provided as a
28
29
30 visual reference. Specimens with a relatively high porosity level between 10 to 15
31
32
33 % showed a strength of 406 ± 32 MPa, while the highly-porous specimens with a
34
35
36 density of 72 to 78 % TD showed strength of 118 ± 6 MPa.

37
38 Attempts were made to evaluate the bulk's Young's modulus of the hafnium carbide
39
40
41 obtained by flexure. First, the data were collected and the porosity has been
42
43
44 identified from the SEM of the top surface of every individual bar after flexure. It is
45
46
47 known that the elastic moduli are quite sensitive to the porosity level [33], and there
48
49
50 are several functions that can describe the mechanical properties as a function of
51
52
53 porosity. We selected a simple exponential function in order to identify the porosity
54
55
56 of the pore-free HfC (**Figure 9**). The modulus of 426 GPa was obtained from such
57
58
59 an analysis. Several individual tests showed slightly higher values of Young's
60
61
62
63
64
65

1
2
3
4 modulus, hence, 426 ± 10 GPa can be considered as a provisional result. The data are
5
6
7 in good agreement with values reported in [13],[15]. However, ref [31], indicated
8
9
10 that the values of 750 GPa can be considered in engineering calculations. Based on
11
12
13 results of this study, we consider such a value as an overestimation (data were
14
15
16 derived from highly porous specimens). Data of ref [22] 360 ± 29 GPa for 98.5 % TD
17
18
19 monolithic HfC are too low, as such values were evaluated for specimens with a ~15
20
21 % porosity in this study.
22

23
24 **Figure 10** illustrates the change in Young's modulus with temperature for grade D.
25
26
27 Noticeably, all the recorded curves for these ceramics only had a linear elastic part
28
29
30 even at 2000 °C, the data of refs. [31,34–36] illustrate trends in Young's modulus
31
32
33 change with temperature for HfC and ZrC.
34
35
36
37

38 *3.4 High-temperature deformation behavior*

39
40
41 **Figure 11** illustrates the temperature dependence of the strength of the hafnium
42
43
44 carbide bulks prepared in the present study and previously reported flexural tests
45
46
47 results [10–13]. It is worthy to note that for coarse grained ceramics, i.e., grades C
48
49
50 and D, only a minor difference in the strength at the different temperatures was
51
52
53 observed. Furthermore, the flexural strength data can be approximated by a quasi-
54
55
56 linear relationship as presented in **Figure 11** using the dotted lines for the 95%
57
58 confidence intervals.
59
60
61
62
63
64
65

1
2
3
4 The data for hafnium carbide ceramics with finer grains resulted in different shapes
5
6
7 of the strength vs temperatures curves. Grade A, hafnium carbide with the finest
8
9
10 grain size, showed a steadily decline in the strength versus temperature, which
11
12
13 became more clear after the 1600 °C tests. That being said, the strength at 1000 °C
14
15
16 was considerably higher than for the coarser grade C or grade D (400 vs 300 MPa).
17
18
19 Grade B showed a very strange behavior as the strength increased up to 1600 °C,
20
21
22 followed by a rapid decline up to 2000 °C. This behavior has been previously
23
24
25 observed for carbide ceramics [7,9], and can be explained as follows. The increase
26
27
28 in strength can be attributed to the ongoing microplastic deformation inside the HfC
29
30
31 grains despite the fact that the loading curves for these ceramic bulks were linear
32
33
34 before fracture.

35
36 At temperatures exceeding 1600 °C an intergranular fracture becomes the dominant
37
38
39 fracture mechanism. Such change in the macroscopic fracture mechanism, as a rule,
40
41
42 leads to a decrease in strength [37]. However, as one can see from the data or ref.
43
44
45 [10], the strength may further increase, which can be understood by the
46
47
48 accommodation of plastic deformation inside the grains and activation of the grain
49
50
51 sliding [3]. Based on results of this study, is that the grain sliding contribution should
52
53
54 decrease with the larger grains, hence slightly higher strength were observed for
55
56
57 coarse grains.

In order to obtain additional high-temperature deformation data of the monolithic hafnium carbide specimens, we attempted to determine the yielding behavior of the SPSed highly-dense HfC at different strain rates. Previously, it has been mentioned that different carbide ceramics may have a different dependences on the strain rate [20,38]. Most noticeably, Darolia and Archbold [20] reported that for polycrystalline zirconium carbide, a positive variation of 0.2 yield strength may allow one to estimate the activation energy for the carbide at elevated temperatures.

Using the methodology proposed in [20], we attempted this approach for hafnium carbide with different grain sizes. **Figure 12** shows the dependence of the yield strength of the grade A carbide as a function of the strain rate at 1800 °C, 1900 °C and 2000 °C. **The Figure 12 (c) shows the dependence of the yield strength of the HfC carbide as a function of the strain rate at 2000 °C for grade A for selected strain rates. For clarity we show only one full strain-stress curve is presented.** The data on the 0.02 yield strength can be approximated using a linear regression with the inverse slope values between 4 and 5. In contrast, that hafnium carbide bulks with a grain size exceeding 25 μm had a weak strain rate dependence (grade C), or the strain rate did not affect the yield point for the attempted strain rates (grade D, **Figure 13**). The analysis of grade B is in general agreement with the data of ref [20]. As a result, the values were observed in [20], which are provided as a reference in **Figure 14**. As noted by Kelly and Rowcliffe for TiC [38], and by Darolia and Archbold [20] for

1
2
3
4 ZrC, one can quantitatively calculate the activation volume for the strength-related
5
6
7 tests at elevated temperatures as:

$$V = kT \frac{\Delta \ln \dot{\epsilon}}{\Delta \sigma}.$$

13 where the k is the Boltzmann constant, T is the absolute values of the temperature
14 of the test, $\dot{\epsilon}$ is the plastic strain rate, and σ is the yield strength. The activation
15
16 volume can be obtained by plotting the yield strength vs logarithm of the strain rate
17

56
57
58
59
60
61
62
63
64
65
(Figure 14), which yields values of 368 \AA^3 and 352 \AA^3 at $1800 \text{ }^\circ\text{C}$ and $2000 \text{ }^\circ\text{C}$,
respectively. The data for ZrC [20] presented in **Figure 14** would yield 373 \AA^3 at
 $1800 \text{ }^\circ\text{C}$. Assuming the lattice parameter from the XRD measurements as 4.64 \AA ,
one can expect that such a volume is proportional to $\sim 30b^3$ (b is a $a/2$ [1-10]). For
clarity, the tantalum carbide values of $50b^3$ to $55b^3$ have been reported [39].

Knowing both the yield strength and activation volume allows one to estimate the
activation energy for the high-temperature deformation from the plot of $(\ln \sigma +$
 $\sigma V/kT)$ versus $1/T$. Such efforts results in the activation energy of $370 \pm 15 \text{ kJ/mol}$.

Table 1 summarizes the creep and diffusion data by various methods for HfC and
ZrC [20,40–42]. Based on the values of the activation energy, one can presume that
similar to other carbides, these values may indicate that the diffusion of carbon in
metal (metal carbide) is the rate limiting process. Nevertheless, one cannot
underestimate the proximity of the activation energy reported in this study and that
reported by Zubarev for ZrC [20] (370 kJ/mol , and 368 kJ/mol , respectively).

1
2
3
4 Although studies [20] and [3] indicate the same mechanism, one can note the
5
6
7 difference in the activation energy (368 kJ/mol [3], 501±19 kJ/mol [20]), which can
8
9
10 be explained by a different temperature range, grain sizes, carbon deficiency, or
11
12
13 loading methods (constant loading in [3]).
14

15 We emphasized that hafnium carbide bulks with grain sizes exceeding 25 μm
16
17
18 prepared from the same raw powder showed that the loading rate did not affect the
19
20
21 yielding at elevated temperatures. In fact, for grade D (**Figure 15**), high-temperature
22
23
24 fracture was identical above 1600 °C. Considering the intergranular fracture as the
25
26
27 main mechanism at elevated temperatures, one can expect the strength of
28
29
30 350±15 MPa for grades C, D is the strength of the grain boundaries at elevated
31
32
33 temperature. This strength shows how good grains of HfC are sintered together using
34
35
36 SPS. One can see that grades A or B after the flexural tests show a strength smaller
37
38
39 than coarser grains (**Figure 11**). One should mind that temperature/dwell for the
40
41
42 consolidation of grade D and A were 2100 °C/15 min and 1840 °C/6 min,
43
44
45 respectively. Hence, one may expect that specimens consolidated at a longer dwell
46
47
48 will have a better performance at elevated temperatures. In terms of possible
49
50
51 practical applications at elevated temperatures, where plastic deformation should be
52
53
54 somehow avoided or limited [3], hafnium carbide ceramics with coarser grains and
55
56
57 elastic fracture at 2000 °C may be recommended.
58
59
60
61
62
63
64
65

1
2
3
4 Based on the theoretical viewpoint, the high-temperature strength behavior can be
5 directly connected to the grain size, as similar observations has been made for Al₂O₃
6 [43], UO₂ [44], and ZrC [3]. Although in each individual case a different mechanism
7 may contribute, the general observation that may clarify the results for HfC is that
8 the grain sliding contribution should decrease with the larger grains; same is true for
9 the consolidation of coarse powders.
10

11
12
13
14
15
16
17
18
19
20
21 Canon et al. [44] summarized that a decrease in strength at elevated temperatures
22 can be directly attributed to grain-boundary sliding, while the rate-controlling
23 mechanism for the grain deformation would be caused by dislocations. As noted by
24 Coble [45] in his discussion about deformation of oxides, the thickness affected by
25 dislocations may be considered as 10²–10⁴ Å (0.01 to 1 μm). As expected, if the
26 grain size being an order of magnitude larger than the apparent widths of the
27 boundaries (or thickness within which diffusion is enhanced), it can be expected that
28 grain-boundary diffusion should be rate controlling. The data of Zubarev [3]

29
30
31
32
33
34
35
36
37
38
39
40
41
42
43
44 summarized in **Table 1** for HfC and ZrC are for 11 μm and 14–30 μm, respectively.

45
46
47 Hence one can view the grain size as a factor contributing to the resistance to
48 deformation is [3,41,46–48]. For carbides the grains coarser than 15 μm as in [46–
49 48] would mean that the bulk (lattice) diffusion mechanisms will be dominant and
50 the contribution of the grain-boundary diffusion would be minimal. Andrievskii et
51 al. [41] suggested that based on the diffusion profiles of ¹⁴C in carbides, the
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1
2
3
4 contribution of the grain-boundary diffusion was at the detection limit during the
5
6
7 creep tests above 2200 °C. Hence, the activation energy evaluated for the high-
8
9
10 temperature deformation tests in flexure indicated the rate limiting process should
11
12
13 be that of carbon in the carbide.
14
15
16
17

18 **Conclusions**

19
20
21 In summary, hafnium carbide bulks consolidated using spark-plasma sintering
22
23
24 despite possessing a high brittleness (fracture toughness 2.2 MPa m^{1/2}) and relatively
25
26
27 high hardness of 15 GPa, show an adequate level of flexural strength (up to 600
28
29
30 MPa). The room temperature flexural strength followed a Hall-Petch like
31
32
33 dependence suggesting that a higher strength can be further obtained after mastering
34
35
36 the densification and grain growth. Coarse grained monoliths showed a weak
37
38
39 dependence on the strain rate during high-temperature tests at 1600 °C–2000 °C.
40
41
42 The results for ceramics with a grain size below 20 µm indicated a positive
43
44
45 dependence of the yield strength vs strain rate. This allowed us to evaluate the
46
47
48 activation energy for high-temperature deformation of 370 kJ/mol which is
49
50
51 comparable to previous reports on HfC and ZrC ceramics.

Table 1 Creep and diffusion data by various methods for HfC and ZrC

System	Method	Qa, kJ/mol	Temperature range, °C	Reference
¹⁴ C in HfC	Isotope tracing	545±54	2200–2800	[41]
¹⁴ C in α-Hf	Isotope tracing	312	1120–1760	[40]
¹⁴ C in β-Hf	Isotope tracing	167	1820–2130	[40]
Hf in HfC	Diffusion theory	764	-	[42]
HfC0.98	Compressive creep	833 ^{*1}	2400– 2700	[3]
ZrC0.94	Compressive creep	678 ^{*1}	2200–2600	[3]
ZrC0.93	Tensile creep	720 ^{*2}	2200–2400	[3]
ZrC0.98	Creep in flexure	368 ^{*3}	1800–2200	[3]
ZrC0.94	Flexure	501±19 ^{*3}	1600–1800	[20]
HfC0.99	Flexure	370±15	1800–2000	This study

The mechanism identified by authors of the original study (ref. [3]) is presented:

^{*1} Creep controlled by bulk diffusion of Me in carbide

^{*2} Dislocation-driven creep controlled by bulk diffusion of C in carbide

^{*3} Dislocation glide controlled by bulk diffusion of C in carbide
